Abstract:

Background:

Radiotherapy (RT) often activates the cyclic GMP-AMP synthase (cGAS) stimulator of interferon response cGAMP interactor (STING) signaling pathway and induces systemic immunotherapy effects by triggering immunogenic cell death (ICD) in various solid tumors. However, RT-induced ICD usually falls short in eradicating distant tumors because of moderate anti-tumor immune responses.

Methods:

In this study, Mn-ZIF-8 nanoparticles and microneedles were prepared, and their physical and chemical properties were characterized. Subsequently, *in vitro* experiments using B16 and A375 cutaneous melanoma cell lines were conducted to investigate the radiosensitivity characteristics of Mn-ZIF-8 and its mechanism for enhancing RT efficacy. Moreover, mouse models bearing primary and distant B16 cutaneous melanoma were established to clarify the immunomodulatory effect and antitumor efficacy of Mn-ZIF-8 microneedles when combined with RT and immunotherapy.

Results:

A percutaneous delivery method based on soluble microneedles (MNs) with Mn^{2+}-loaded, X-ray-responsive zeolite imidazolate frame-8 (ZIF-8) was designed. This microneedle-based drug delivery system, combined with RT, promoted the radiosensitivity of cutaneous melanoma and reinforces ICD by augmenting STING pathway activation. Furthermore, after X-ray irradiation, Mn-ZIF-8 MNs continuously released Mn^{2+} in the tumor to enhance cGAS-STING activation. This promoted dendritic cell maturation and antigen presentation,

45 and potentiated a T cell mediated immune response. Thus, the local and systemic immune

46 effects induced by RT were amplified when combined with immune checkpoint inhibitors.

47 **Conclusion:**

48 The microneedle patches with X-ray-responsive, rapid dissolution and controlled release

49 abilities have the potential to enhance the radioimmunotherapy efficacy for cutaneous

50 melanoma.

51

54

Introduction

Radiotherapy (RT) not only directly kills tumor cells through DNA damage caused by ionizing radiation, but also induces tumor regression beyond the irradiation field by activating an immune response, termed the "abscopal effect" of RT [1-3].This effect is mainly caused by immunogenic cell death (ICD), in which dendritic cells (DCs) recognize and present exposed tumor antigens to activated T cells to generate a systemic anti-tumor immune response, thereby diminishing metastatic cancer in non-irradiated areas [4, 5]. However, the anti-tumor immune response induced by RT alone is usually insufficient to eliminate distant tumors [6, 7]. The immunosuppressive tumor microenvironment (TME) often limits the therapeutic effects of RT [8-10]. Therefore, it is critical to develop novel RT strategies to reshape the TME to overcome RT resistance and immunosuppression.

Immune checkpoint inhibitors (ICIs) can reinvigorate T cells in an immunosuppressive tumor ecosystem, thus playing an anti-tumor role. They are used widely in clinical treatment; however, the response rate is less than 30% in melanoma [11]. At the same time, based on the heterogeneity, complexity, and diversity of tumors, the current treatment strategy for cancer is increasingly inclined toward combination therapy [12]. The significant immunostimulating effect of RT has resulted in clinical studies showing that patients who received RT as well as ICI treatment achieved more significant survival benefit than those that received RT alone [13-17]. Most studies aimed to activate systemic immune-mediated antitumor effects through radiation-induced *in situ* tumor vaccines [18-20]. However, the synergistic effect of combination therapy is not obvious in practice. Therefore, how to improve the efficacy of combination therapy has become an urgent issue in clinical practice.

Many nanomaterials have been developed to overcome radio-resistance and reverse immunosuppression by alleviating hypoxia, activating stimulator of interferon response cGAMP interactor (STING), promoting immune checkpoint blocking, regulating metabolic processes, and remodeling the extracellular matrix (ECM) and fibroblasts [21-24]. Activation of the immune system by radiation is largely dependent on the activation of the immune system "accelerator", namely the cyclic GMP-AMP synthase (cGAS)-STING pathway [25]. Radiation therapy exerts its effects by damaging tumor cell DNA structures, leading to abnormal accumulation of DNA damage fragments in the cytoplasm [5]. The DNA sensor cGAS recognizes and binds cytoplasmic DNA fragments, catalyzing cGAMP synthesis which then activates STING as a second messenger, triggering downstream signaling cascades that induce potent immune responses [26, 27]. However, the activation of the cGAS-STING pathway mediated by these DNA fragments is inherently limited due to the low cytoplasmic transport efficiency of negatively charged DNA fragments, which restricts their binding to cGAS protein [28]. Notably, while radiation damages DNA, it also upregulates the DNA exonuclease Trex1, which degrades radiation-induced cytoplasmic DNA, thereby attenuating its immunogenicity [7]. Therefore, improving the sensitivity of cGAS recognition of cytosolic dsDNA in DCs using agonists could synergistically benefit cGAS-STING activation to enhance RT and immune checkpoint blockade (ICB) efficacy [30, 31]. The metal ion Mn^{2+} is an effective activator of the cGAS-STING pathway, stimulating the production of type I interferon (IFN), significantly promoting the maturation and antigen presentation of DCs and macrophages, enhancing the activation of $CD8^+$ T cells, and triggering specific anti-tumor immunity [32, 33]. Mn-deficient mice were reported to have severely reduced numbers of

99   tumor-infiltrating cytotoxic $CD8^+$ T cells and thus lost control of tumor progression and

100 metastasis [34]. More importantly, a completed phase 1 clinical trial (Clinical Trials. Gov.

101 Identifier: NCT03991559) combining Mn^{2+} and anti-programmed cell death 1 (PD-1)

102 antibodies (αPD-1) showed encouraging clinical outcomes in patients with advanced

103 metastatic solid tumors [34]. To ensure efficient STING pathway activation, various

104 TME-responsive Mn-based nanomaterials have been developed as STING nanoagonists

105 [35-38]. In addition, Mn is an essential nutritional trace element with well-studied toxicology

106 to human health that plays critical roles in many physiological processes, including innate and

107 adaptive antitumor immune responses [39, 40]. Based on these findings, the sustained release

108 of Mn^{2+} as a cGAS-STING agonist to synchronize with sensitized RT-mediated ICD

109 accumulation offers a potential solution to tackle the above-mentioned challenge in treating

110 solid tumors. ZIF-8 is an X-ray-responsive metal-organic framework (MOF), which is

111 composed of zinc ions coordinated with 2-methylimidazole, with good biocompatibility. ZIF-8

112 has extremely low systemic toxicity and sensitive pH-responsive biodegradability; therefore,

113 it can be used as a drug carrier, with wide applications in bioimaging and cancer therapy [41,

114 42]. In addition, a study showed that ZIF-8 has radiological response characteristics, which

115 can achieve controlled drug release [43]. Therefore, the development of ZIF-8 frame

116 nanocomposites based on Mn^{2+} is expected to enhance the effect of RT combined with

117 immunotherapy.

118   Microneedles, which can directly pierce the stratum corneum and deliver drugs to the

119 deep skin layer in a painless manner through microporous channels, have attracted wide

120 attention because of their simple administration, economy, good biocompatibility, and no

needle waste [44-47]. In the treatment of superficial tumors, MNs can be adapted in size and

shape to conform to the irregularities of the tumor lesions, enabling precise drug

administration and reduced dosage, which consequently lowers the potential risk of systemic

toxicity [48, 49]. Additionally, MNs serve as a "mechanical adjuvant", stimulating the release

of pre-immunological cytokines in skin tissue [50, 51], thereby enhancing the local immune

response and having the potential to augment immunogenic cell death induced by RT.

Herein, we report that Mn-ZIF-8-loaded MNs act as potent radiosensitizers and

cGAS-STING agonists to exert enhanced radio-immunotherapy for cutaneous melanoma

(**Scheme 1**). After the MNs are applied to cutaneous melanoma, they rapidly dissolve and

release Mn-ZIF-8 nanoparticles (NPs), which act as radiosensitizers to induce ICD and

accumulate DNA damage in the tumor. After radiation, Mn^{2+} is continuously released into

tumor tissues to promote DC maturation by activating the cGAS-STING cascade signaling

pathway, including inducing the phosphorylation of STING and interferon regulatory factor 3

(IRF3), and upregulating interferon beta (IFN-β) expression. The maturation of DCs and

integration with ICB further evokes robust antitumor immunity to combat primary and

metastatic tumors. Therefore, efficient radiosensitization synchronized with a cGAS-STING

pathway stimulation-based immunoregulation strategy is highly likely to optimize cancer

radioimmunotherapy in clinical practice.

Results

Synthesis and Characterization of Mn-ZIF-8

The preparation process of Mn-ZIF-8 is shown in Scheme 1 and Figure S1. The ZIF-8

143   skeleton was modified by doping Mn^{2+} and Mn^{4+} ions, resulting in the synthesis of Mn-ZIF-8.

144   The transmission electron microscopy (TEM) images revealed that ZIF-8 retained its original

145   structure of a rhomboid dodecahedron shape after modification with Mn^{2+} and Mn^{4+} (Figure

146   1A). The zeta potentials (Figure 1B) were almost consistent and indicating that Mn ion doping

147   did not change the basic properties of the ZIF-8 NPs and the hydrodynamic diameters of ZIF-8

148   and Mn-ZIF-8 (Figure 1C) were 124.5, 136.9, 113.7, and 123.3 nm. The Mn and Zn elements

149   were distributed throughout the whole NPs (Figure 1D). The area of Mn equated to a doping

150   rate of 20%, which was consistent with the theoretical value, and the elemental ratio of Mn:Zn

151   was determined to be 96.38:3.62. Consistent with a previous report [52], the X-ray diffraction

152   (XRD) patterns of ZIF-8 and Mn-ZIF-8 revealed characteristic diffraction peaks (Figure 1E).

153   Moreover, with an increased Mn doping rate, the main peak (011) of Mn-ZIF-8 gradually

154   shifted to the right, probably because of the replacement of Zn ions with Mn in the ZIF-8

155   skeleton. X-ray photoelectron spectroscopy (XPS) was conducted to analyze the chemical

156   composition and valence states of Mn. Figure 1F shows the main corresponding peaks of Zn,

157   Mn, and O, and the Mn 2p XPS spectra are shown in Figure 1G. The peak of Mn $2p_{3/2}$ could

158   be divided into two characteristic peaks (640.7 and 642.8 eV), which were consistent with the

159   reported data for Mn^{2+} and Mn^{4+}, respectively. This suggests that Mn^{2+} and Mn^{4+} can be found

160   in the structure of Mn-ZIF-8: the ratio of Mn^{2+} was 50.05% and the ratio of Mn^{4+} is 49.95%.

161   As Figure 1H shown, at pH = 5.5, Mn^{2+} was nearly completely released within approximately

162   3 h, demonstrating that Mn-ZIF-8 MNs can rapidly release Mn^{2+} in the acidic tumor

163   microenvironment to exert antitumor effects. In contrast, at pH = 7.4, the cumulative release

164   rate after 24 h was only about 23%, suggesting minimal leakage into normal tissues to cause

165 undesired side effects.

166

Anticancer Effect and Radiosensitization of Mn-ZIF-8 *In Vitro*

Initially, we evaluated the impact of Mn-ZIF-8 and its constituent elements at varying concentrations, in conjunction with a 6Gy X-ray irradiation, on the survival rate of B16 cells (epithelial-like cells isolated from skin of a mouse with melanoma). We used the CCK-8 assay to evaluate the radiosensitization efficiency of Mn-ZIF-8 with different Mn^{2+} doping ratios (5%, 10%, and 20%). The experimental data clearly show that at all tested radiation doses (0, 2, 4, and 6 Gy), Mn(20%)-ZIF-8 at 20 μg/mL exhibited the best radiosensitization effect, with significantly lower cell survival rates compared to the 5% and 10% doping groups (Figure 2A and Figure S2). This dose-dependent enhancement confirms a positive correlation between Mn^{2+} content and radiosensitization efficacy. Furthermore, under 6 Gy irradiation, we treated B16 cells with different doping ratios of Mn-ZIF-8 (20 μg/mL) and measured key proteins involved in the STING pathway. The Western blot results demonstrated that the 20% Mn-ZIF-8 group induced higher levels of p-STING and p-IRF3 expression compared to the 5% and 10% groups, suggesting that a higher Mn content more effectively activates the cGAS-STING pathway (Figure S3). Therefore, ZIF-8 and Mn-ZIF-8 at 20 μg/mL (referred to Mn(20%)-ZIF-8) were chosen for further investigation. Mn-ZIF-8 exhibited significant cytotoxicity after irradiation (IR) treatment in B16 and A375 melanoma cells, as shown by cell couniting kit-8 (CCK8) assays (Figure 2B). Furthermore, we conducted clonogenic assays using human keratinocyte HaCaT cells to assess the biocompatibility of Mn-ZIF-8. Treatment with 20 μg/mL Mn-ZIF-8 demonstrated no significant reduction in colony formation

efficiency compared to PBS control (Figure S4). This result clearly indicates that Mn-ZIF-8 exhibits minimal toxicity toward normal cells. By contrast, combined Mn-ZIF-8 and IR treatment could effectively inhibit colony formation of B16 and A375 melanoma cells (Figure 2C). Then, the DNA damage induced by IR in B16 and A375 melanoma cells was evaluated using immunofluorescence staining of γ-H$_2$AX. Mn-ZIF-8 markedly increased the formation of IR-induced γ-H$_2$AX foci (Figure 2D). Taken together, these results indicated Mn-ZIF-8 could increase the sensitivity of melanoma cells to RT and induce obvious DNA damage under RT.

Mn-ZIF-8 Enhanced ICD and the Activation of the STING Pathway Induced by RT *In Vitro*

Radiotherapy can activate the immune system against tumors by inducing ICD, a specific cell death modality, which would trigger the release of damage-associated molecular patterns (DAMPs), such as calreticulin (CRT) exposure, high mobility group box 1 (HMGB1) release, and ATP secretion, thereby increasing the immunogenicity of the TME [53, 54]. Therefore, we investigated the effects of Mn-ZIF-8 on RT-induced ICD by examining CRT exposure, HMGB1 release, and ATP secretion. Significant expression of CRT was observed after treatment with Mn-ZIF-8 in combination with IR (6 Gy), in sharp contrast to other groups (Figure 3A-B). Furthermore, treatment with Mn-ZIF-8 in combination with IR (6 Gy) enhanced the release of HMGB1 from the cell nuclei as well as ATP production in B16 and A375 melanoma cells (Figure 3C-E). These results indicated that treatment with Mn-ZIF-8 in combination with RT would significantly promote the ICD of tumor cells, which is a

209   prerequisite for a subsequent antitumor immune response. Additionally, we also observed that

210   Mn-ZIF-8 treatment combined with X-ray irradiation (6 Gy) significantly enhanced

211   mitochondrial superoxide levels in B16 cells compared to either X-ray alone or X-ray + ZIF-8

212   treatments, as quantified by mitochondrial superoxide fluorescence intensity measurements

213   (Figure S5). This confirms that Mn-ZIF-8 can potentiate radiotherapy through enhanced ROS

214   generation.

215   The STING pathway is intricately linked to the generation of the antitumor immune

216   response. It has been established that free Mn^{2+} ions significantly amplify cGAS-STING

217   signaling cascade activation, exerting a comprehensive effect, ranging from boosting the

218   synthesis of cGAMP to enhancing cGAMP-STING binding affinity [55, 56]. Next, we

219   evaluated the capacity of Mn-ZIF-8 to activate the STING pathway *in vitro*. STING

220   pathway-related proteins were examined using western blotting. As shown in Figure 3F,

221   increased levels of phosphorylated STING and IRF3 were observed after treatment with

222   Mn-ZIF-8 in combination with IR (6Gy), indicating that Mn-ZIF-8 contributed to activation

223   of the STING pathway in melanoma cells induced by RT. Moreover, Mn-ZIF-8 significantly

224   promoted IFN-β secretion after IR treatment, further indicating effective activation of STING

225   pathway by Mn-ZIF-8 (Figure 3G).

226

227   **Fabrication and Characterization of Mn-ZIF-8 MNs**

228   Centrifugal micro-perfusion method was used to prepare the MNs (Figure S6). The

229   resultant Mn-ZIF-8 MNs and ZIF-8 MNs were pyramid-shaped and regularly arranged in a 12

230   × 12 array (Figure 4A and Figure S7). The MNs had a needle height of 1200 μm, a base width

231 of 300 μm, and a tip-to-tip interspace of 800 μm, located on a 1 × 1 cm patch (Figure 4B and

232 Figure S8). In addition, elemental mapping of the main and top (Figure 4C) views of the MNs

233 was scanned to study the distribution of Mn and Zn ions in the MNs. The majority of Mn and

234 Zn ions were observed to be distributed in the needle tips, probably owing to the concentration

235 of Mn-ZIF-8 in the needle tips under centrifugal force. Next, we further validated the stability

236 of the microneedles during both preparation and storage processes. First, we conducted

237 morphological comparisons between freshly prepared Mn-ZIF-8 MNs and Mn-ZIF-8 MNs

238 after storage (Figure S9). The results showed that the structural morphology of Mn-ZIF-8

239 nanoparticles was well preserved, without signs of aggregation, deformation, or disintegration,

240 indicating excellent physical stability during fabrication and storage. Second, TEM-EDS

241 elemental analysis demonstrated that the elemental ratios of Zn and Mn remained consistent

242 between the fresh and stored Mn-ZIF-8 MNs, further confirming that the chemical

243 composition and doping structure of Mn-ZIF-8 were not altered throughout the microneedle

244 preparation process (Figure S10). The morphological changes of Mn-ZIF-8 MNs were

245 recorded using optical microscopy, which showed that the MNs were completely dissolved

246 after 8 min of application (Figure 4D). The dissolution behavior of MNs was conducive to the

247 release and diffusion of the drug from the MNs, thereby increasing drug delivery efficiency.

248 The mechanical properties of MNs are a key factor that determines their skin insertion ability.

249 The average fracture forces of Mn-ZIF-8 MNs and ZIF-8 MNs were 0.3305 N/needle and

250 0.3285 N/needle, respectively, indicating that the fracture forces of both MNs are greater than

251 the minimum force (0.1N/needle) required for the MNs to pierce the stratum corneum (Figure

252 4E-F) [57]. The mechanical strength of blank MNs was 0.3052 N per needle which was lower

than that of Mn-ZIF-8 MNs and ZIF-8 MNs (Figure S11). The enhanced mechanical strength of Mn-ZIF-8 MNs and ZIF-8 MNs may be attributed to the electrostatic interactions between the positively charged Mn-ZIF-8/ZIF-8 and negatively charged hyaluronic acid. Simultaneously, we captured morphological images of the microneedles before and after mechanical testing (Figure S12). Hematoxylin and eosin (H&E) staining was performed on rat skin receiving microneedle puncture. Obvious micropores with a depth of 300–340 microns were observed in the H&E-stained skin tissue, indicating that the prepared MNs possess favorable skin penetration capabilities and can successfully deliver drugs to the dermis (Figure 4G and Figure S13). We captured fluorescence images (Figure S14) of IR780-labeled Mn-ZIF-8 microacupuncture at different times after subcutaneous tumor insertion. The drug delivery efficiency is a key factor affecting therapeutic outcomes. Therefore, we compared the drug delivery efficiency of microneedles and intratumoral injection by monitoring the biodistribution of fluorescence-labelled Mn-ZIF-8 nanoparticles. The fluorescence intensity (representing drug retention and sustained release) after intratumoral injection increased rapidly, peaking within 6 hours post-administration, followed by a sharp decline, indicating rapid drug clearance from the tumor site. In stark contrast, MN administration showed a markedly different pharmacokinetic profile: the fluorescence intensity remained relatively stable and high for at least 24 hours post-administration (over 50% fluorescence retention), and subsequently declined slowly, maintaining measurable intensity even at 120 hours (Figure S15).

Antitumor Effects of Mn-ZIF-8 MNs Combined with RT in a B16 Melanoma Xenograft

Mouse Model

To evaluate the anticancer efficacy of Mn-ZIF-8 prodrugs delivered by MNs patches, we implanted B16 melanoma cells subcutaneously in the right lateral thigh area of C57BL/6J mice. Once the tumor reached approximately 100 mm^3, the mice were randomly divided into three groups (n = 5): X-ray (I), X-ray + ZIF-8 MNs (II), and X-ray + Mn-ZIF-8 MNs (III). On the seventh day after tumor implantation, the MNs patches were applied to the tumor site and the tumors were irradiated with X-rays (12Gy) once at 16 hours after Mn-ZIF-8 MNs administration (Figure 5A). The tumor volumes and body weights were monitored every 3 days from tumor implantation until the mice were euthanized. All mice showed a slight weight loss about a week after RT and remained within the normal body weight range during the treatments (Figure 5B). Major organs (heart, liver, spleen, lung, and kidney) from mice were analyzed by H&E staining (Figure S16). No obvious tissue damage or side effects were found in the mouse organs, indicating excellent biosafety. Furthermore, a complete blood panel analysis and serum biochemistry assay (Figure S17) were performed. Notably, almost all the examined indexes were in the normal ranges, suggesting no obvious systematic toxic side effects of the treatment.

Tumor growth was only slightly delayed in the X-ray + ZIF-8 MNs group. However, the tumor growth in the X-ray + Mn-ZIF-8 MNs group was significantly delayed (Figure 5C-H). Mice receiving different treatments were sacrificed on the 16th day after tumor implantation and the collected tumors were sliced for immunohistochemistry (IHC) staining or dissociated into cell suspensions for flow cytometry analysis. Immunohistochemical staining for marker of proliferation Ki-67 (Ki-67) and H&E staining in tumor slices showed that the most cell death

297 and the least cell proliferation occurred in the X-ray + Mn-ZIF-8 MNs treatment group (Figure

298 5I), further revealing the Mn-ZIF-8 MNs-induced RT enhancement.

299 Relevant studies have shown that RT-induced ICD of tumor cells and STING pathway

300 activation can activate DCs and further enhance anti-tumor immune activity. We demonstrated

301 *in vitro* that Mn-ZIF-8 can promote IR-induced ICD and STING pathway activation. Then, we

302 verified the underlying mechanism of the antitumor responses triggered by treatment with

303 X-ray + Mn-ZIF-8 MNs combined with RT *in vivo*. First, the IHC results indicated that X-ray

304 + Mn-ZIF-8 MNs treatment drove much higher CD4$^+$ T cell infiltration and exhibited the

305 highest level of CD8$^+$ T cells, but no significant difference of the infiltration of regulatory T

306 cells (Tregs) was found in tumors. We examined the expression of granzyme B (GZMB)—a

307 key effector molecule of activated cytotoxic T cells for tumor killing [58]. The Mn-ZIF-8 MNs

308 + X-ray group showed significantly higher GZMB-positive areas compared to X-ray alone and

309 ZIF-8 MNs + X-ray, which correlates with our observed increase in CD8$^+$ T cell infiltration

310 (Figure 5I and Figure S18). The maturation of DCs in the inguinal lymph nodes was detected

311 using flow cytometry. The mice treated with X-ray + Mn-ZIF-8 MNs could effectively

312 enhance DC maturation in lymph nodes, thus enhancing their antigen presentation ability

313 (Figure 5J and Figure S19). Later, the proportions of CD4$^+$ T cells (Figure 5K and Figure S20),

314 CD8$^+$ T cells (Figure 5L and Figure S21) and Tregs cells (Figure 5M and Figure S22) in

315 tumors were also measured using flow cytometry, and the results were approximately

316 coincident with the IHC results. Meanwhile, treatment with X-ray + Mn-ZIF-8 MNs increased

317 the infiltration of CD8$^+$ T cells and CD4$^+$ T cells in the spleen (Figure 5N-O and Figure

318 S23-24). Collectively, X-ray + Mn-ZIF-8 MNs could promote DC maturation and CD8$^+$ T cell

infiltration, thus inducing robust systemic antitumor immunity *in vivo*.

Mn-ZIF-8 MNs Plus RT Potentiates Systemic Antitumor Immunity Induced by ICB

To investigate the systemic immune responses and the therapeutic potential of X-ray + Mn-ZIF-8 MNs combined with ICB, we established a bilateral B16 subcutaneous tumor model on C57BL/6J mice. B16 cells were subcutaneously injected into the left side of mice 2 days after the inoculation of primary tumors in the right side. Once the right tumor reached approximately 100 mm^3, the mice were randomly divided into three groups (n = 5): X-ray (I), X-ray + αPD-1 (II), and X-ray + αPD-1 + Mn-ZIF-8 MNs (III). On the seventh day after tumor implantation, the MNs patches were applied to the primary tumor site and the primary tumors were irradiated with X-rays (12Gy) once at 16 hours after application. The mice of groups II and III were intraperitoneally (i.p.) injected with αPD-1 (10 mg/kg) on days 8, 10, and 12 after tumor implantation (Figure 6A). The tumor volumes and body weights were monitored every 2 days from tumor implantation until the mice were euthanized. The primary and distant tumor growth were recorded and analyzed. Treatment with X-ray + αPD-1 + Mn-ZIF-8 MNs showed the strongest growth control of both primary and distant tumors compared with that of the other groups (Figure 6B-F and Figure S25).

Next, mice receiving different treatments were sacrificed on the 16th day after tumor implantation and the collected primary and distant tumors were sectioned for IHC staining or dissociated into cell suspensions for flow cytometry analysis. First, the maturation of DCs in the inguinal lymph nodes on the primary tumor side was detected using flow cytometry. The mice treated with X-ray + αPD-1 + Mn-ZIF-8 MNs showed effective enhancement of DC

maturation in their lymph nodes, thus enhancing the antigen presentation ability (Figure 6G

and Figure S26). The flow cytometry results indicated that treatment with X-ray + αPD-1 +

Mn-ZIF-8 MNs drove much higher infiltration of CD4$^+$ T and CD8$^+$ T cells in the primary

tumors; however, no significant difference of the infiltration of Tregs in the primary tumors

was found for three groups (Figure 6H and Figure S27-29). The findings regarding CD4$^+$ T

and CD8$^+$ T cell populations in distant tumors closely mirrored those observed in the primary

tumors (Figure 6I and Figure S30-31). However, treatment with X-ray + αPD-1 + Mn-ZIF-8

MNs reduced the percentage of Tregs in the distant tumors (Figure 6I and Figure S32). Later,

the proportions of CD4$^+$ T cells, CD8$^+$ T cells, and Tregs cells in the primary and distant

tumors were also measured using IHC, and the results were approximately coincident with the

flow cytometry results (Figure 6J and Figure S33). Likewise, the X-ray + αPD-1 + Mn-ZIF-8

MNs group demonstrated significantly enhanced GZMB expression in both primary and

distant tumors compared to other groups (Figure 6J and Figure S33). Consistently, H&E and

immunohistochemical Ki67 staining of primary and distant tumor slices showed the most cell

death and the least cell proliferation in the group treated with X-ray + αPD-1 + Mn-ZIF-8

MNs (Figure 6J and and Figure S33). Collectively, these results illustrated that Mn-ZIF-8 MNs

combined with X-ray treatment triggered a strong systemic immune response, which

effectively synergized with ICB to eliminate both primary and metastatic tumors.

Discussion and Conclusion

In summary, we proposed a rapidly dissolving MNs patch loaded with high bioactivity

molecular sieve imidazole skeleton sealed with Mn^{2+} nanoparticles. we specifically

demonstrated that Mn-ZIF-8-based microneedles potentiate radiation-induced ICD and enhance activation of the cGAS-STING pathway, leading to increased infiltration of cytotoxic $CD8^+$ T cells and maturation of dendritic cells — key features of an effective anti-tumor immune response. These immunological mechanisms are not unique to melanoma but are shared across many "cold" tumors that exhibit limited baseline immune infiltration, such as breast cancer, pancreatic cancer, and colorectal cancer [40]. Indeed, STING agonists have been investigated as broad-spectrum immune adjuvants in multiple solid tumor models beyond melanoma [59]. Additionally, our delivery platform — X-ray-responsive Mn-ZIF-8 nanoparticles in dissolving microneedles — was engineered to provide localized radiosensitization and immune modulation, a strategy applicable to many superficial or accessible solid tumors. For example, squamous cell carcinoma, head and neck cancers, and cutaneous metastases from breast or gynecologic cancers are all relevant clinical targets where localized treatment via MNs could be readily adapted [60]. Therefore, the Mn-ZIF-8-loaded MNs demonstrated significant potential to improve the efficacy of radio-immunotherapy in cutaneous melanoma. The potential clinical applications of Mn-ZIF-8 MNs are particularly compelling. Mn^{2+} ions have already demonstrated promising results in clinical trials for solid tumors as STING pathway agonists, further validating the clinical relevance of Mn-based therapies [34]. ZIF-8 itself, due to its excellent biocompatibility, and biodegradability, has also emerged as a clinically relevant carrier platform, enhancing therapeutic precision and controlled drug release [61]. Additionally, microneedle systems have been advancing into clinical trials, particularly for dermatological diseases and vaccines, establishing a solid foundation for clinical adoption due to their ease of use, patient compliance, and reduced

biohazard risk compared to traditional injections [62]. However, despite these promising aspects, significant translational challenges remain. These include ensuring consistent batch-to-batch quality and reproducibility of biomaterials, optimizing large-scale manufacturing processes, and establishing robust sterilization methods without compromising therapeutic efficacy [63]. Moreover, regulatory pathways for combination products involving novel nanomaterials (like ZIF-8 and metal-ion-based therapeutics) and delivery systems (like MNs) require extensive validation and clinical safety profiles, which are currently limited and require thorough evaluation [64]. Long-term biocompatibility, biodegradation kinetics, potential immunogenicity, and off-target effects also represent significant considerations before clinical implementation.

Experimental Section

Materials

Mn(NO$_3$)$_2$·4H$_2$O, Zn(NO$_3$)$_2$·6H$_2$O, Methanol, Ethanol, Gelatin, and IR780 were obtained from Macklin Industrial, Inc. (Shanghai, China). 2-methylimidazole was obtained from Aladdin Industrial, Inc. (Shanghai, China). Hyaluronic acid (HA) and PVP K90 were purchased from BASF (Ludwigshafen, Germany).

Synthesis of Mn-ZIF-8 NPs

We weighed out 0.5 mmol (20%), 0.25 mmol (10%) or 0.125 mmol (5%) of Mn(NO$_3$)$_2$·4H$_2$O, and 2 mmol of Zn(NO$_3$)$_2$·6H$_2$O, and dissolved them together in 20 mL of methanol to obtain mixed solution 1. We weighed out 40 mmol of 2-methylimidazole and dissolved it in 80 mL of methanol. Using a pipette, mixed solution 1 was added slowly to the

407   2-methylimidazole methanol solution under gentle magnetic stirring at room temperature.

408   After the addition was complete, the mixture was stirred at room temperature for 4 h, and then

409   then placed at 50 °C for 1 h. The mixture was centrifuged at 13000 g at room temperature for

410   10 minutes, the precipitate was washed with methanol twice, and then concentrated to obtain

411   20 mL of Mn-ZIF-8 NPs. Compositions of ZIF-8 and Mn-ZIF-8 are provided in Supporting

412   Information: Table S4.

413   *Synthesis of ZIF-8 NPs*

414   We weighed out 2.5 mmol of $Zn(NO_3)_2.6H_2O$ and dissolved it in 20 mL of methanol to

415   obtain Solution 1. The remaining steps are the same as those in *Synthesis of Mn-ZIF-8 NPs*.

416   *Fabrication and characterization of Mn-ZIF-8 MNs*

417   All MNs in this study were prepared using a polydimethylsiloxane (PDMS) micromold.

418   The needle tips were fabricated using a 1:1 (v/v) mixture of 350 mg/mL hyaluronic acid

419   solution and Mn-ZIF-8 methanol solution. The base layer was prepared from

420   polyvinylpyrrolidone (PVP K90) ethanol solution (312.5 mg/mL). 200 μL of the needle

421   solution was dispensed into each PDMS mold well, followed by centrifugation (2,080 × g, 5

422   min, 4-10 °C) to ensure complete microchannel filling. Residual solution on the mold surface

423   was removed using an aluminum scraper. A second centrifugation (2,080 × g, 30 min, 4-10 °C)

424   was performed to compress the needle matrix and initiate partial drying. 300 μL of base

425   solution was added to each well and centrifuged (2,080 × g, 5 min, 4-10 °C) for uniform

426   distribution. The male mold was air-dried at room temperature for 48 h. The resulting

427   Mn-ZIF-8 MNs were then carefully demolded and stored in a desiccator until use.

428   *Mechanical characteristics of the MNs*

429　　　　The mechanical properties of the MNs array were evaluated using a Texture analyzer

430　　(Stable micro systems, UK). Each MNs patch tested was attached to a flat plate with the tip of

431　　the needle facing up. A force perpendicular to the plate was applied at a constant speed of 0.5

432　　mm/min and the compression distance was set to 1 mm.

433　　*Insertion capacity of MNs*

434　　　　MNs were placed vertically on the skin surface of the abdomen of SD rats, the MNs base

435　　layer was pressed vertically for 2 min. The MNs were then removed, the skin at the

436　　administration site was clipped, and immediately soaked in 4% paraformaldehyde fixing

437　　solution. H&E staining was performed after paraffin-embedded skin sections were obtained.

438　　*In vitro degradation experiment*

439　　　　Mn-ZIF-8 MNs was placed into a dialysis bag (MWCO=3500) and injected with 2 mL of

440　　PBS (pH=5.5/pH=7.4). After sealing the dialysis bag, 10 mL of PBS (pH=5.5/pH=7.4) was

441　　placed into the dialysis bag. The release temperature was set at 37 °C and the rotational speed

442　　was set at 200 rpm. 1 mL of dialysate was taken at 1, 3, 6, 12, 24 h and the corresponding

443　　preheated PBS was supplemented at the same time. The content of Mn^{2+} was detected by

444　　ICP-OES (Agilent 720ES).

445　　*Small animal in vivo imaging*

446　　　　Three C57BL/6 male mice were selected for back hair removal. After anesthesia,

447　　IR780-labeled (20%) Mn-ZIF-8 MNs were either pressed onto the tumor-bearing skin of each

448　　mouse for 2 minutes or injected intratumorally into the subcutaneous tumor., and the

449　　fluorescence signals of the back skin of the mice at different time points (1, 2, 6, 12, 24, 48, 72,

450　　96, and 120 hours) were collected using a small animal *in vivo* imaging system (PerkinElmer,

451 USA).

Cell Culture

453 The mouse melanoma cell line B16 and the human melanoma cell line A375 were

454 respectively cultured in Roswell Park Memorial Institute (RPMI) 1640 medium (Gibco, Grand

455 Island, NY, USA) and Dulbecco's Modified Eagle's Medium (DMEM, Gibco) containing

456 10% fetal bovine serum (FBS, ExCell Bio, Shanghai, China) and 1% penicillin-streptomycin

457 (NCM Biotech, Newport, RI, USA) at 37 °C in a 5% CO_2 atmosphere incubator.

Cell Viability Assay

459 The percentage of the viable cells was detected using CCK8 assays. B16 and A375 cells

460 (1×10^3 per well) were seeded into 96-well plates and allowed to attach for 6–8 hours. Then,

461 100 μL of complete 1640 or DMEM was added to support cell growth. Cells were exposed to

462 additional media containing nanoparticles at different concentrations for 16 h and then

463 subjected to X-ray irradiation at the indicated doses. After culture for another 24 h, 10 μL of

464 the CCK8 (5 mg.mL^{-1}) stock solution (GlpBio, China) was added to each well and the plate

465 was incubated for 2 h at 37 °C. The absorbance in each well was measured using a

466 Multifunctional plate reader (TECAN, Männedorf Switzerland) at a wavelength of 450 nm.

467 The relative percentage of the untreated cells was adjusted to represent 100% cell viability,

468 and then the relative viabilities of the treated cells were calculated and plotted as cell survival

469 curves using GraphPad Prism 9.5 software (GraphPad Inc., La Jolla, CA, USA).

Colony Formation Assay

471 B16 and A375 cells (2×10^3 per well) were seeded into six-well plates with complete

472 medium and allowed to grow for 6–8 hours. Then, 2 mL of complete 1640 or DMEM was

473 added to support cell growth. The plates were incubated with nanoparticles at the indicated

474 concentrations for 16 h and then with irradiated at the indicated doses of X-rays, followed by

475 further culture for about 10 days. Subsequently, the cells were gently rinsed with

476 phosphate-buffered saline (PBS) three times before being fixed with 4% paraformaldehyde for

477 15 min at room temperature. After staining with crystal violet (0.1%) for 30 min, the colonies

478 were imaged under a stereomicroscope, analyzed using ImageJ (NIH, Bethesda, MD, USA),

479 then the cell clonal formation rate was plotted as a histogram using GraphPad Prism software.

480 *In Vitro DNA Damage Study*

481 B16 and A375 cells (5×10^4 per well) were seeded into 24-well plates with complete

482 medium and allowed to grow for 6–8 hours. Then, 0.5 mL of complete 1640 or DMEM was

483 added to support cell growth. The plates were incubated with nanoparticles at the indicated

484 concentrations for 16 h, exposed to X-ray irradiation (2Gy), and then further cultured for 1 h.

485 Subsequently, the cells were gently rinsed with PBS three times and before being fixed with

486 4% paraformaldehyde for 15 min at room temperature. The cells were then washed with PBS

487 three times, incubated with 0.5% TritonX-100 at room temperature for 15 min, washed with

488 PBS twice, submerged in 5% bovine serum albumin (BSA) sealing solution for 1 h, incubated

489 with anti-γ-H$_2$AX antibodies (Cell Signaling Technology, USA) at 4 °C overnight, washed

490 with PBS-Tween20 (PBST) three times, and incubated with Alexa Fluor-conjugated

491 secondary antibodies (Proteintech, Wuhan, China) at room temperature for 1 h. Following

492 three further washes with PBST, the cell nuclei were stained using

493 4′,6-diamidino-2-phenylindole (DAPI, Beyotime Biotech, Shanghai, China). The stained cells

494 were observed under a confocal microscope (Zeiss, Oberkochen, Germany), photographed,

495   and then analyzed using ImageJ. A histogram of the mean cell fluorescence intensity was

496   plotted using GraphPad Prism software.

497   *In Vitro CRT Exposure, HMGB1 Release, and ATP Secretion Assays*

498   B16 and A375 cells (5×10^4 per well) were seeded into 24-well plates with complete

499   medium and allowed to grow for 6–8 hours. Then, 0.5 mL of complete 1640 or DMEM was

500   added to support cell growth. The plates were incubated with nanoparticles at the indicated

501   concentrations for 16 h, exposed to X-ray irradiation (6 Gy), and then further cultured for 24h

502   or 8h. Subsequently, the cells were gently rinsed with PBS three times and fixed with 4%

503   paraformaldehyde for 15 min at room temperature. Then, the cells washed with PBS three

504   times and stained with anti-HMGB1 or anti-calreticulin antibodies at 4 ℃ overnight. Next day,

505   the cells were washed with PBST three times, incubated with fluorescently labeled secondary

506   antibodies at room temperature for 1 h, and washed with PBST three times. The cell nuclei

507   were stained using DAPI. The stained cells were observed under a confocal microscope

508   (Zeiss), photographed, and then analyzed using ImageJ. A histogram of the mean cell

509   fluorescence intensity was plotted using GraphPad Prism software.

510   In a similar experiment, after the cells were treated with RT as above, incubation was

511   continued for 18 h. The cell culture medium was collected, and dying cells in the medium

512   were removed through centrifugation. The supernatants were utilized for quantitative analyses

513   of the ATP content using an ATP assay kit (Beyotime, Shanghai, China). An ATP content

514   histogram was plotted using GraphPad Prism software.

515   *Detection of Mitochondrial Superoxide Generation in vitro*

516   To evaluate mitochondrial reactive oxygen species (ROS) levels *in vitro*, MitoSOX™

Green (Thermo Fisher Scientific) was used as a mitochondria-targeted fluorescent probe for superoxide detection in B16 melanoma cells. A 1 mM MitoSOX™ Green stock solution was prepared by dissolving the contents of one vial in 10 μL of anhydrous dimethylformamide (DMF). Working solution (1 μM) was freshly prepared by diluting 3 μL of the stock solution in 3 mL Hank's Balanced Salt Solution (HBSS) containing calcium and magnesium. After the indicated treatments (X-ray, ZIF-8, Mn-ZIF-8), the culture medium was aspirated, and cells were washed once with pre-warmed HBSS. Each well was then incubated with 1 mL of 1 μM MitoSOX™ Green working solution for 30 minutes at 37 °C in the dark. After incubation, cells were washed three times with pre-warmed HBSS to remove residual probe. Cells were imaged using a fluorescence microscope equipped with FITC channel (excitation 488 nm, emission 510 nm). Mitochondrial superoxide levels were quantified using ImageJ software based on mean fluorescence intensity in the FITC channel.

Western Blotting

Levels of proteins related to the STING signaling pathways in B16 and A375 cells incubated with ZIF-8 or Mn-ZIF-8 NPs with or without X-ray were analyzed using western blotting. Total cellular protein extracts were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), transferred onto polyvinylidene difluoride membranes. After blocking with 5% BSA, the membranes were incubated with primary antibody overnight at 4 °C. The membranes were then incubated with secondary antibodies for 60 min. The immunoreactive protein bands were incubated with an ECL kit (Applygen, Beijing, China) and analyzed using an imaging system (Tanon 5200 Multi, Shanghai, China). Greyscale analysis of immunoblot bands was performed using ImageJ

539   software. Antibody information is provided in Supporting Information: Table S1.

540   *Cytokine Detection*

541   B16 cells (1×10^5 per well) were seeded into 6-well plates with complete medium and

542   allowed to grow for 6–8 hours. Then, 2 mL of complete 1640 medium was added to support

543   cell growth. The plates were incubated with nanoparticles at the indicated concentrations for

544   16 h, exposed to X-ray irradiation (6 Gy), and then further cultured for 48 h. Cell supernatants

545   were collected and subjected to ELISA for IFN-β detection (Mei Mian Biotechnology Co.,

546   Ltd., Jiangsu, China). An IFN-β content histogram was plotted using GraphPad Prism

547   software.

548   *Mouse Model and Treatment*

549   All animal experiments were approved by the Experimental Animal Protection, Welfare,

550   and Ethics Committee of Nanfang Hospital, Southern Medical University under the protocol

551   number IACUC-LAC-20231022-001. Female 6-week-old C57BL/6 mice were obtained from

552   Guangdong Zhiyuan Biological Pharmaceutical Company and housed under SPF conditions at

553   the Experimental Animal Center of Nanfang Hospital. The animals were maintained under a

554   controlled environment (temperature 20-24 °C, humidity 40-70%, 12 h light/dark cycle) with

555   ad libitum access to standard chow and water. To ensure experimental reproducibility and

556   reduce selection bias, mice were randomly assigned to different treatment groups using a

557   random number generator (GraphPad Prism 9). Tumor-bearing mice were included in the

558   study only after the subcutaneous tumor volume reached approximately 80-100 mm³ to ensure

559   baseline homogeneity. All procedures adhered to the National Institutes of Health Guide for

560   the Care and Use of Laboratory Animals, which outlines standards for humane endpoints,

561 anesthesia, and euthanasia protocols. B16 cells (5×10^5) were injected subcutaneously into the

562 right lateral thigh area of the C57/BL6 mice. B16 cells (3×10^5) were subcutaneously injected

563 in the left side of the mice on the second day. On day 6, when the right tumor reached

564 approximately 100 mm^3, the animals were randomly assigned to the control and different

565 treatment groups. On the seventh day after tumor implantation, the MNs patches were applied

566 to the tumor site. On day 8, all mice were anesthetized by intraperitoneal (i.p.) injection of

567 pentobarbital sodium (20 mg/kg), and the tumors were irradiated once with X-ray (12 Gy)

568 using the Small Animal Radiation Research Platform of Southern Hospital radiotherapy

569 department (512 cGy/min, 6-MeV-ray beam; Siemens, Munich, Germany). An anti-mouse

570 PD-1 monoclonal antibody (mAb) (Bio X Cell, Lebanon, NH, USA) was administered

571 intraperitoneally (200 μg per mouse) on days 8, 10 and 12. The tumor volumes and body

572 weights were monitored every 2-3 days from tumor implantation until the mice were

573 euthanized. The tumor volume was calculated using the following formula: tumor volume

574 (mm^3) = width^2 (mm^2) × length (mm) × 0.5. After 16 or 18 days, the mice were sacrificed, and

575 the tumors and spleens were weighed. Animals were euthanized when they showed signs of

576 imperfect health or when the size of tumors exceeded 2000 mm^3.

577 *In Vivo Safety Evaluation*

578 The *in vivo* toxicity of ZIF-8 or Mn-ZIF-8 MNs under irradiation was evaluated in healthy

579 C57BL/6 mice (6 weeks old). The grouping and other parameters were consistent with the *in*

580 *vivo* antitumor efficacy tests. The body weights of the mice were recorded until day 18. Blood

581 samples were collected on day 18, and blood cells counts were determined. Then, the blood

582 biochemical values, including the levels of serum alanine transaminase (ALT), aspartate

583 transaminase (AST), total bilirubin (TBIL), blood urea nitrogen (BUN), uric acid (UA), and

584 creatinine (CREA), were analyzed to investigate potential hepatic and renal toxicity. On the

585 day 18, the major organs (heart, liver, spleen, lung, and kidney) were removed and analyzed

586 using H&E staining.

587 *Flow Cytometry*

588 　　The therapeutic impact of ZIF-8 or Mn-ZIF-8 MNs under radiation was assessed. In a

589 unilateral tumor-bearing mouse model, at day 18 post-implantation, the animals were

590 euthanized, and samples of the tumor, spleen, and ipsilateral inguinal lymph nodes were

591 harvested. For the bilateral tumor-bearing model, on day 16 post-implantation, the animals

592 were euthanized, and both the primary and metastatic tumors were collected. Subsequently,

593 single-cell suspensions from lymph nodes, spleen, and tumors were prepared using an enzyme

594 cocktail (comprising neutral protease, collagenase type II, and hyaluronidase) (BD

595 Biosciences, San Jose, CA, USA). The cells from the inguinal lymph nodes were stained with

596 anti-CD11c-PerCP-Cy5.5, anti-CD86-PE-Cy7, and anti-CD80-BV421 antibodies) for the DC

597 maturation study. Tumor cells were stained with anti-CD3-PerCP-Cy5.5, anti-CD4-BV510,

598 anti-CD8-FITC, anti-anti-forkhead box P3 (FoxP3)-BV421, and anti-CD45-PE antibodies and

599 then analyzed using flow cytometry. Antibody information is provided in Supporting

600 Information: Table S2. The gating strategy is provided in Figure S34.

601 *Histopathology and Immunohistochemistry*

602 　　Biopsied tissue samples were subjected to H&E staining to facilitate histological

603 evaluation. For the immunohistochemical procedures, both primary and metastatic lesions

604 were extracted from rodents across various treatment arms and preserved in formaldehyde

solution (4%, w/v). Post-paraffin embedding, the tumor tissues deparaffinized and rehydrated, preceding heat induced antigen retrieval. The tumor tissue sections were stained with primary antibodies (Abcam, Cambridge, MA, USA) comprising anti-Ki67, anti-CD4, anti-CD8, FoxP3 and GZMB and then reacted with horseradish peroxidase (HRP)-labeled secondary antibodies (DAKO, Glostrup, Denmark). Images were captured using an automatic slide scanner after visualization using a 3,3′-Diaminobenzidine (DAB) substrate kit (DAKO). Antibody information is provided in Supporting Information: Table S3.

Statistical Analysis

All data are displayed as mean values ± standard deviation (SD). The significance of the statistical differences among the groups was determined using one-way ANOVA and Tukey's multiple comparisons test. The threshold for statistical significance was as follows: *, p values < 0.05; **, p values < 0.01; ***, p values < 0.001; and ****, p values < 0.0001. All statistical analyses were carried out with GraphPad Prism 9.5 software).

Scheme 1. Schematic Illustrations. (i) Schematic illustration of the preparation process of Mn-ZIF-8 and (ii) the proposed mechanism of Mn-ZIF-8-mediated radiosensitization and STING pathway-dependent antitumor immunity for enhanced the radioimmunotherapy efficacy.

821

Figure 1. Construction and characterization of Mn-ZIF-8. (A) TEM images of Mn(20%)-ZIF-8 at different magnifications. (B) Zeta potentials and (C, n = 3 per group) Hydrodynamic diameters of ZIF-8 and Mn-ZIF-8. (D) Elemental mapping images of Mn(20%)-ZIF-8. (E) The XRD patterns of ZIF-8 and Mn-ZIF-8. (F) The XPS survey spectra of Mn(20%)-ZIF-8. (G) The XPS spectra of Mn 2p. The blue line represents the fitted baseline, the purple and green lines correspond to the fitted peaks for Mn^{4+} and Mn^{2+}, and the red line shows the final fitted curve. (H) The cumulative release profile of Mn^{2+} from Mn-ZIF-8 MNs under different pH conditions. The data are presented as the mean ± SD.

830

Figure 2. Effect of Mn-ZIF-8 on melanoma cell proliferation and dsDNA damage. (A) Effect

of Mn-ZIF-8 at different concentrations and its components in combination with radiotherapy

(6 Gy) on the viability of B16 cells (*n* = 6 per group). (B) Effect of PBS, ZIF-8, and Mn-ZIF-8

834 in combination, with or without radiotherapy (B16, 6 Gy; A375, 4Gy), on the proliferation of

835 melanoma cells, as assessed using the CCK8 assay ($n = 5$ per group). (C) Effect of PBS, ZIF-8,

836 and Mn-ZIF-8 in combination, with or without different doses of radiotherapy (2, 4, and 6 Gy),

837 on the proliferation of melanoma cells, as assessed using a colony formation assay (B16, $n = 4$

838 per group; A375, $n = 3$ per group). (D) Effect of PBS, ZIF-8, and Mn-ZIF-8 in combination,

839 with radiotherapy (2Gy), on the dsDNA breaks in melanoma cells, as evaluated using

840 immunofluorescence staining of γ-H$_2$AX. Scale bar = 10 μm. The data are presented as the

841 mean $\pm$ SD. *$P < 0.05$, **$P < 0.01$, ***$P < 0.001$, ****$P < 0.0001$.
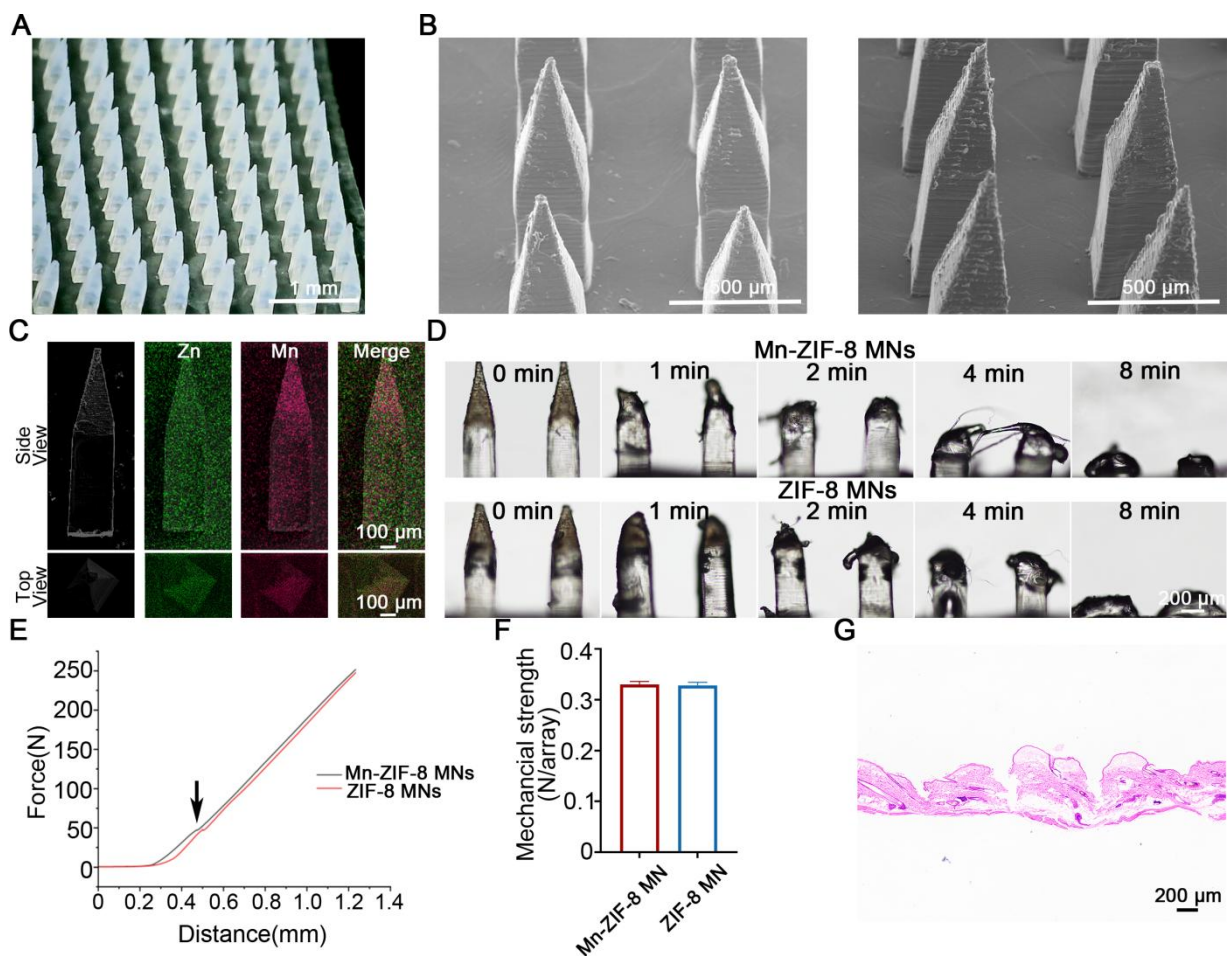

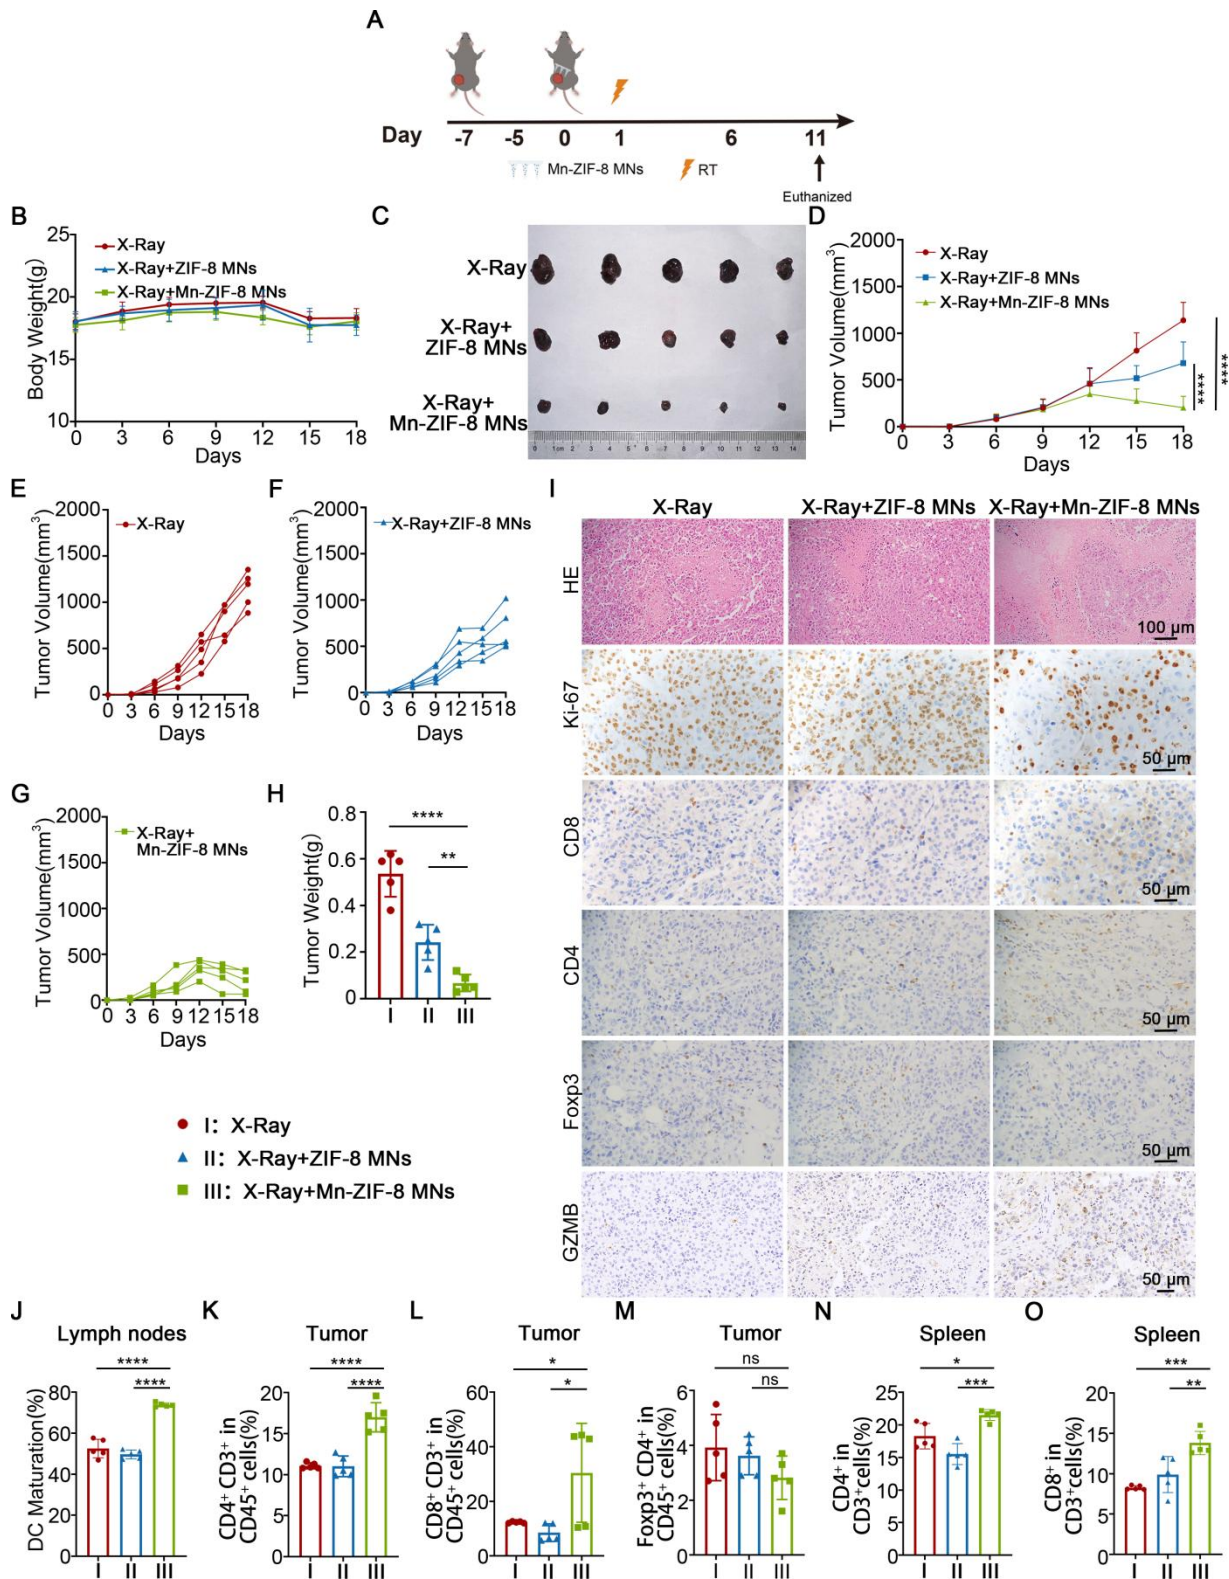

842

Figure 3. Mn-ZIF-8 enhanced ICD and the activation of the STING pathway induced by RT *in vitro*. (A) and (B) Quantification of CRT fluorescence intensities and representative fluorescence images of melanoma cells subjected to various treatments ($n = 5$ per group). (C) and (D) Quantification of HMGB1 fluorescence intensities and representative fluorescence images of melanoma cells subjected to various treatments ($n = 5$ per group). Scale bar = 10 μm. (F) Western blotting analysis of the activation of cGAS-STING in melanoma cells subjected to various treatments. ELISA analysis of the secretion of (E) ATP and (G) IFN-β from melanoma cells subjected to with various treatments ($n = 3$ per group). The data are presented as the mean ± SD. *$P < 0.05$, **$P < 0.01$, ***$P < 0.001$, ****$P < 0.0001$.

Figure 4. Construction and characterization of MNs loaded with Mn-ZIF-8. (A) Photograph of the Mn(20%)-ZIF-8 MNs array. (B) SEM images of Mn(20%)-ZIF-8 and ZIF-8 MNs. (C) Main view and top view of elemental mapping images of Mn(20%)-ZIF-8 MNs. (D) Solubility of Mn(20%)-ZIF-8 MNs. (E) The force-displacement curves of Mn(20%)-ZIF-8 and ZIF-8 MNs. Arrow: Fracture point of MNs. (F) Mechanical strength of the force per individual needle (N per needle) (*n* = 3 per group). (G) H&E staining of the rat skin punctured with Mn(20%)-ZIF-8 MNs. The data are presented as the mean ± SD.
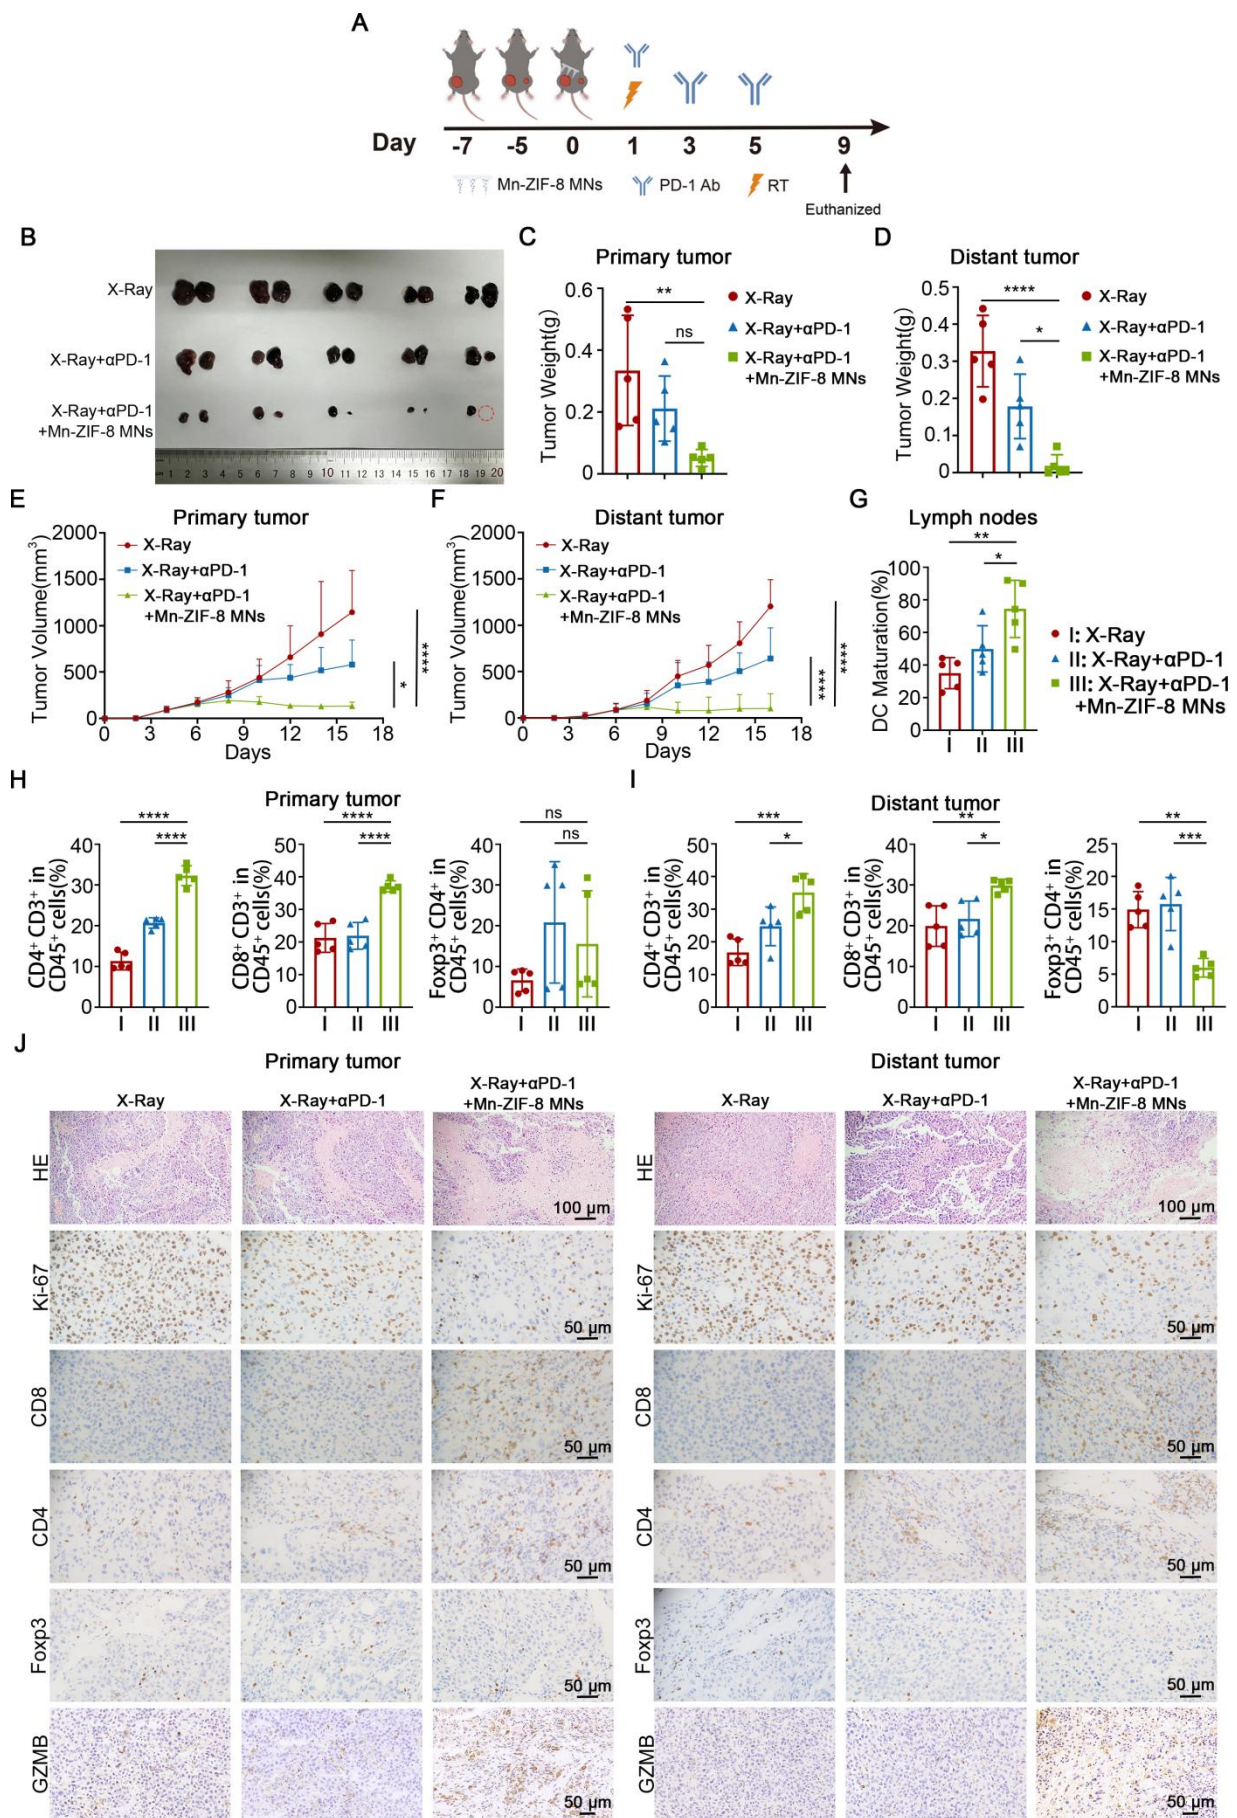

41

Figure 5. Antitumor effects of Mn-ZIF-8 MNs in a B16 melanoma xenograft mouse model. (A)

Experimental timeline for the treatment of B16 tumor-bearing C57BL/6J mice. (B) Body

weight curve of mice during treatment. (C) Photograph of B16 tumors isolated from the mice

866   on day 18. (D) Tumor growth curve of mice subjected to different treatments. (E) and (F) and

867   (G) Individual tumor growth curves of mice after different treatments. (H) Weights of tumors

868   isolated from the mice on day 18. (I) H&E staining of tumor tissues and IHC images showing

869   Ki67, $CD4^+$ T, and $CD8^+$ T cell infiltration, Foxp3 and GZMB expression after the indicated

870   treatments. (J) Quantitative analysis of mature DCs ($CD80^+$ $CD86^+$ in $CD11c^+$ cells) in

871   inguinal lymph nodes adjacent to tumors after treatment. (K–M) Percentages of

872   tumor-infiltrating $CD4^+$ T, $CD8^+$ T, and Treg cells. (N) and (O) Percentages of

873   spleen-infiltrating $CD4^+$ T and $CD8^+$ T cells. The data are presented as the mean ± SD; $n = 5$

874   per group. $*P < 0.05$, $**P < 0.01$, $***P < 0.001$, $****P < 0.0001$.

875

877 **Figure 6**. Mn-ZIF-8 MNs combined with RT plus ICB elicited systemic antitumor immunity.

878 (A) Experimental timeline for the treatment of bilateral B16 tumor-bearing C57BL/6J mice. (B)

879 Photograph of primary (left) and metastatic (right) B16 tumors isolated from the mice on day

880 16. (C) and (D) Weights of primary tumors and distant tumors isolated from the mice on day

881 16. (E) and (F) Primary tumors and distant tumor growth curves of the mice after different

882 treatments. (G) Quantitative analysis of mature DCs (CD80$^+$ CD86$^+$ in CD11c$^+$ cells) in

883 inguinal lymph nodes adjacent to primary tumors after treatment. (H) Percentages of primary

884 tumor-infiltrating CD4$^+$ T, CD8$^+$ T, and Treg cells. (I) Percentages of distant tumor-infiltrating

885 CD4$^+$ T, CD8$^+$ T, and Treg cells. (J) H&E staining of bilateral tumor tissues and IHC images

886 showing Ki67, CD4$^+$ T, and CD8$^+$ T cell infiltration, and Foxp3 and GZMB expression after

887 the indicated treatments. The data are presented as the mean ± SD; $n = 5$ per group. *$P < 0.05$,

888 **$P < 0.01$, ***$P < 0.001$, ****$P < 0.0001$.
